Empirical Peak Ground-Motion Predictive Relations for Shallow Earthquakes in Greece

by A. A. Skarlatoudis, C. B. Papazachos, B. N. Margaris, N. Theodulidis, Ch. Papaioannou, I. Kalogeras, E. M. Scordilis, and V. Karakostas

Abstract In the present article new predictive relations are proposed for the peak values of the horizontal components of ground acceleration, velocity, and displacement, using 619 strong motion recordings from shallow earthquakes in the broader Aegean area, which are processed using the same procedure in order to obtain a homogeneous strong motion database. The data set is derived from 225 earthquakes, mainly of normal and strike-slip focal mechanisms with magnitudes $4.5 \le M \le 7.0$ and epicentral distances in the range 1 km $\leq R \leq 160$ km that have been relocated using an appropriate technique. About 1000 values of peak ground acceleration (PGA), velocity (PGV), and displacement (PGD) from horizontal components were used to derive the empirical predictive relations proposed in this study. A term accounting for the effect of faulting mechanisms in the predictive relations is introduced, and the UBC (1997) site classification is adopted for the quantification of the site effects. The new relations are compared to previous ones proposed for Greece or other regions with comparable seismotectonic environments. The regression analysis showed a noticeable (up to $\sim 30\%$) variance reduction of the proposed relations for predicting PGA, PGV, and PGD values compared to previous ones for the Aegean area, suggesting a significant improvement of predictive relations due to the use of a homogeneous strong motion database and improved earthquake parameter information.

Introduction

Empirical predictive attenuation relations are a fundamental tool for seismic hazard assessment. Such relations are based on the recorded peak ground motions using appropriate instruments (e.g., accelerographs) and are expressed as mathematical functions relating the observed quantity to earthquake source parameters, the propagation path, and the local site conditions. So far, much effort has been made in this field, and a large number of predictive relations for peak ground motion have already been published. These relations usually refer to large regions such as the northwest United States, Canada (Milne and Davenport, 1969; Campbell, 1985; Boore et al., 1993), or Europe (Ambraseys and Bommer, 1991; Ambraseys, 1995; Ambraseys et al., 1996; Rinaldis et al., 1998), but also to smaller regions with high levels of seismicity, such as Greece or Italy (Chiaruttini and Siro, 1981; Papaioannou, 1986).

Two major efforts for estimating empirical predictive relations were previously made in Greece, the first one by Theodulidis (1991) and Theodulidis and Papazachos (1992) and the latest by Margaris *et al.* (2002). The occurrence of recent strong disastrous earthquakes close to urban areas, the continuous increase of the number of strong motion record-

ings in Greece, the new more accurate automatic methods for digitization of analog recordings, and the new relocation techniques resulting in more accurate hypocenter determination raised the need for new improved predictive relations. Therefore, our aim is to propose new predictive relations for Greece by incorporating the most recent information available.

The study area (Fig. 1a) is seismically one of the most active regions in western Eurasia. The most dominant feature of the area is the Hellenic trench, where subduction of the eastern Mediterranean lithosphere takes place under the Aegean microplate. Shallow as well as intermediate-depth earthquakes with magnitudes up to about 8.0 have occurred in this area (e.g., Papazachos and Papazachou, 2002). To the north of the trench, the sedimentary part of the Hellenic arc (Dinarides–Hellenides mountains–Crete–Rhodes) represents the accretionary prism. Moving further north we can identify other typical elements of a subduction system, namely the south Aegean basin (Sea of Crete) and the volcanic arc. In the north Aegean the North Aegean trough, which is the continuation of the North Anatolia fault system into the Aegean, controls the regional tectonics and exhibits large

Figure 1. (a) Map of the study area where the main morphotectonic features are also noted. (b) Map of the available focal mechanisms and epicenters of the earthquakes used in this study.

strike-slip faults, whereas the remaining back-arc area is dominated by approximately north–south extension (e.g., Papazachos *et al.*, 1998, 1999).

Data Used

The data used in this article consist of 1000 peak ground-motion values, corresponding to 225 mainly normal and strike-slip faulting, shallow earthquakes in Greece. This data set was selected from the entire database of the available accelerograms in Greece (Institute of Engineering Seismology and Earthquake Engineering [ITSAK], www.itsak.gr, and National Observatory of Athens [NOA], www.gein.noa.gr) that spans the period 1973–1999. The selected records satisfy at least one of the following criteria: (a) the earthquake that triggered the instrument should have a moment magnitude of $\mathbf{M} \ge 4.5$; (b) the strong motion record should have PGA $\ge 0.05g$, independent of the earthquake magnitude; or (c) the record has PGA < 0.05g, but another record with PGA $\ge 0.05g$ should be available for the same earthquake.

The need for higher accuracy in the earthquake location routines used in Greece has led to the development of a relocation method that incorporates not only recent developments of the earthquake location software but also new time delays for P_n and S_n waves for the broader Aegean area, estimated using data from local experiments (Skarlatoudis, 2002; Skarlatoudis et al., 2003). This approach involves correction of the seismic-wave travel times at regional stations based on a calibration with well-located local earthquakes. From the comparison of the expected and the observed travel times of seismic waves, we calculated "absolute" residuals for each one of the regional stations located within the area of interest. These absolute residuals were processed through an inversion technique, which resulted in the estimation of time corrections for each one of the $1^{\circ} \times 1^{\circ}$ square windows into which the examined area had been divided. The data processing and relocation procedure was described in detail in Skarlatoudis (2002) and Skarlatoudis et al. (2003). Using this relocation method a new catalog with accurate earthquake hypocenter parameters (especially for focal depths) was compiled. The errors of this catalog were reduced to 9.8 \pm 9.1 km for the horizontal error 3.0 \pm 6.5 km for focal depths, and a root mean square (rms) error of 1.0 ± 0.2 sec. The importance of this relocated catalog for the results obtained in the regression analysis is examined in the present study. In Table 1 the earthquakes that produced the strong motion data set used in this article are listed.

The continuously increasing number of analog strong motion records from different institutions in Greece during recent years imposed the need of a database with homogenously processed strong motion data. In order to create this database, all the strong motion records were automatically digitized at 600 dots per inch scanning resolution. From the comparison of the Fourier amplitude spectra (FAS) of the components with the FAS of the fixed traces of the accelerogram the characteristic frequencies of a digital bandpass filter were computed. This filter was applied to the accelerograms in order to remove the noise introduced during the digitization and the processing of the records (Skarlatoudis et al., 2002). This filtering procedure succeeded in removing noise, especially in the low-frequency range that mostly affects velocities and displacements (due to the integration that is used for their computation from acceleration). Depending on the individual signal-to-noise spectral ratio, a different frequency range is available for each strong motion record-

(continued)

The magnitudes of the earthquakes in our database come from the catalog of the geophysical laboratory of Ar-

istotle University of Thessaloniki (Papazachos *et al.*, 2000). The size of the earthquakes in this catalog is expressed in a scale equal or equivalent to the moment magnitude, **M** (Hanks and Kanamori, 1979). For earthquakes lacking original moment magnitude estimates, the equivalent moment magnitude was used, as it is calculated from the equation (Papazachos *et al.*, 1997)

$$M_{\rm W}^* = 0.97 M_{\rm LGR} + 0.58, \tag{1}$$

where $M_{\rm LGR}$ is the local magnitude calculated from the trace amplitudes of the Wood–Anderson and short-period instruments of the Institute of Geodynamics of the National Observatory of Athens and the geophysical laboratory of Aristotle University of Thessaloniki. Moment magnitude was confirmed to be a suitable independent variable in defining predictive relations for the Aegean area (Papazachos *et al.*, 2001a), in agreement with similar observations worldwide (Joyner and Boore, 1981). Furthermore, the linearity of equation (1) has been shown (Papazachos *et al.*, 1997; Margaris and Papazachos, 1999) to be valid for the examined $M_{\rm LGR}$ range ($4.0 \le M_{\rm LGR} \le 6.5$). This is important issue in order to avoid introducing nonlinear effects in the predictive relations from magnitude-conversion relations (e.g., Fukushima, 1996; Papazachos *et al.*, 2001a).

The effect of source mechanism in predictive attenuation relations was recognized and pointed out many times by many researchers. McGarr (1984), Campbell (1984, 1997), Sadigh et al. (1993), Boore et al. (1997), and Anooshehpoor and Brune (2002) showed that thrust faults exhibit higher PGAs than those from other source mechanisms. Accordingly all the available information on the focal mechanisms of the earthquakes of our data set was collected from Papazachos and Papazachou (2002), from Papazachos et al. (2001c), as well as from the online catalog of the institutes Istituto Nazionale di Geofisica (I.N.G.), Eidgenössische Technische Hochschule (E.T.H.), and Harvard. For 67 earthquakes fault-plane solutions were available from the previous catalog. An effort to quantify the previous results and include them in the relations proposed by this article has been made. Earthquakes were classified in three categories of normal, strike-slip, and thrust faulting using the plunges of the P and T axes according to Zoback (1992). Beach-ball symbols in Figure 1b denote the fault-plane solutions, while gray circles denote the epicenters of the remaining earthquakes of our data set. These earthquakes were also categorized in the three categories, using current knowledge about the geotectonic environment for the regions where they occurred (Papazachos et al., 1998, 1999, 2001b).

Figure 2 shows the distribution of epicentral distance, R, against moment magnitude, \mathbf{M} , of the earthquakes used in the study for normal, strike-slip, and thrust faulting. It is observed that a correlation exists between these two parameters, introducing some difficulties in defining predictive attenuation relations. In fact, for small magnitudes, $4.5 \leq \mathbf{M} \leq 5.0$, the existing recordings are mainly distributed over

Figure 2. Distribution of the data in terms of moment magnitude, **M**, and epicentral distance, *R*, for (a) normal, (b) strike-slip, and (c) thrust faulting. The trigger level plus one standard deviation cut-off distance limit proposed by Fukushima and Tanaka (1990) and the corresponding trigger level (upper curve)/ trigger level plus one standard deviation (lower curve) limits derived from the present study attenuation curves are also shown by dashed line and gray-shaded area, respectively (see text for explanation).

small epicentral distances ($R \le 40$ km). On the contrary, large-magnitude events are mostly recorded at intermediate and long distances. Furthermore, for earthquakes with $\mathbf{M} > 6.0$ there is a lack of observations in the near field (R < 20 km). Figure 3 shows the distribution of PGA values as a function of epicentral distance (Fig. 3a) and magnitude \mathbf{M} (Fig. 3b), respectively. A dense coverage for distances up to 40 km is observed for PGA values less than 100 cm/sec². Similar remarks can be made for $\mathbf{M} < 6.0$.

Figure 3. Distribution of the peak ground acceleration, PGA, as a function of (a) the epicentral distance, R, and (b) moment magnitude, \mathbf{M} , for the strong motion records used in the present work.

An important point to be considered in the determination of predictive relations is the effect of record truncation at large distances. This problem is imposed by the trigger threshold of accelerographs (typically \sim 3–5 cm/sec²), which excludes lower-level acceleration data from the analysis (as they are not recorded) and may lead to the introduction of bias at large distances in cases of unusually high accelerations due to, for example, the presence of high-Q zones (e.g., Fukushima, 1997). It must be noted that such high accelerations at large distances are usually observed from intermediate-depth or deep subduction events, which were specifically excluded from this analysis. However, in order to avoid such bias, Joyner and Boore (1981) and Fukushima and Tanaka (1990) have suggested rejecting data at distances further from the trigger level or the trigger level plus one standard deviation, respectively. Such a procedure involves adoption of an attenuation relation in order to define the trigger-level distance threshold for each examined magnitude. In Figure 2 the dashed line corresponds to the limits proposed by Fukushima and Tanaka (1990), while the gray-shaded area corresponds to the trigger level (5 cm/sec², upper curve) and trigger level plus one standard deviation (~ 10 cm/sec², lower curve) for the mean predictive relation defined later in the present work. It is evident that all the data lie within the acceptable magnitude–distance area, while only 14 points (2% of our data set) are within one standard deviation from the theoretically estimated trigger threshold limit. After tests we found that excluding these data did not change the result presented later in the regression analysis; hence we can safely conclude that record truncation at large distances does not affect the analysis of the present data set.

In order to classify the local site conditions of the recording stations, we adopted the classification proposed by NEHRP (1994) and UBC (1997), classifying them in the five Universal Building Code categories, namely, A, B, C, D, and E. The classification was performed by using geotechnical information for the sites where such information was available (Klimis et al., 1999). For the remaining stations, information from the geological map of the specific area was used. In our case, the vast majority of recording stations that were finally adopted in this study corresponded to categories B, C, and D. Specifically, 19 recording stations were classified in category B, 68 in C, and 25 in D. Very few sites (six) having geotechnical/geological characteristics between A and B were also included in category B. In Table 2 the classification of site conditions of the recording stations used is presented.

Data Regression and Results

The equations examined in the regression analysis (e.g., Campbell, 1985) were

log
$$Y = c_0 + c_1 \mathbf{M} + c_2 \log(R^2 + h^2)^{1/2} + c_3 F + c_5 S$$
 (2a)

$$\log Y = c_0 + c_1 \mathbf{M} + c_2 \log(R + c_4) + c_3 F + c_5 S,$$
(2b)

where *Y* is the strong motion parameter to be predicted, usually in centimeters per second squared, in centimeters per second, and centimeters if *Y* stands for PGA, PGV, and PGD, respectively, **M** is the moment magnitude, *R* is the epicentral distance, *h* is the focal depth of each earthquake, *S* is the variable accounting for the local site conditions, and *F* is the variable referring to the effect of the faulting mechanism of the earthquakes in the predicting relations. In equations (2a) and (2b) a base-10 logarithm is used and units for *R* and *h* are in kilometers. Scaling coefficients c_0 , c_1 , c_2 , c_3 , and c_5 are to be determined from regression analysis. Coefficient c_4 in equation (2b) accounts for saturation in the near field and is difficult to determine directly by regression analysis on the available data, given its strong correlation with scal-

ing coefficient c_2 , as was shown using appropriate Monte Carlo simulations (Papazachos and Papaioannou, 1997, 1998). For this reason, the value of $c_4 = 6$ km was adopted from Margaris *et al.* (2002), roughly corresponding to the average focal depth of the events used in the present study.

Joyner and Boore (1981) and Fukushima and Tanaka (1990), among others, have proposed various regression methods based on two-step regression procedures for predicting strong ground motion. Those methods aimed to overcome the problem of distance-magnitude correlation that was observed in all strong motion data sets used by previous researchers. More recent studies (Joyner and Boore, 1993) have shown that the stagewise regression methods give similar results with maximum likelihood analysis in one step. Since stagewise regression methods always give results with less precision than maximum likelihood analysis in one step (Draper and Smith, 1981), an optimization procedure based on the least-squares method in one step using the singular value decomposition method (Lanczos, 1961) was used in this article. Such an analysis allows controlling the stability of the optimization and accurate determination and analysis of the errors in the final solution (e.g., Golub and Reinsch, 1970; Press et al., 1992). Furthermore, through this analysis we also expect to overcome and quantify the problems arising from the observed correlation between magnitude and epicentral distance in our data set.

The term for describing site conditions in the predicting equations (2a) and (2b) is expressed as a linear transformation of the classification proposed by NEHRP (1994) and UBC (1997). However, we have also examined the possibility of including separate terms in the predicting equations for site conditions. Therefore, we considered that equations (2) without the site-effect term correspond to soil category B and included two additional terms, one for describing soil category C (S_C) and one for the effect for soil category D $(S_{\rm D})$. Using all the available data, the values obtained for the two coefficients from the regression of equations (2a) and (2b) were $S_{\rm C} = 0.058$ and $S_{\rm D} = 0.125$. From these results it is clear that the S_D value (site effect of D category) is essentially twice the value of $S_{\rm C}$. This result verifies the applicability of the usual assumption for the linearity between the finally adopted variable S in equations (2a) and (2b) and the classification proposed by NEHRP (1994) and UBC (1997). Therefore, the results obtained suggest that the variable S in equations (2a) and (2b) can be assumed to take the values of 0, 1, and 2 for soil categories B, C, and D, respectively.

A similar approach was adopted for the independent variable that describes the effects of focal mechanisms. Initially two different variables, $F_{\rm S}$ and $F_{\rm T}$, were used in equations (2a) and (2b) for strike-slip and thrust faults, respectively, in order to estimate the different contributions for $F_{\rm S}$ and $F_{\rm T}$, considering that strike-slip and thrust faults possibly exhibit higher PGA values than normal faults. The regression showed that the two coefficients were almost equal, revealing that the effects in the predicting equations (2a) and (2b)

from both strike-slip and thrust faults in Greece are similar using the data set of the present study. Therefore, only one variable was used in the regression, in order to describe the higher PGA values from strike-slip and thrust faults, merging $F_{\rm S}$ and $F_{\rm T}$ into a common variable, *F*.

In order to incorporate nonlinear effects of large earthquakes in the proposed equations for strong motion prediction, a second-order magnitude term was also added in predicting equations (2a) and (2b) (e.g., Boore *et al.*, 1993). Unfortunately the small number of large earthquakes in our data set resulted in inadmissible values of magnitude coefficients (positive coefficient for the second-order magnitude term) in the regression analysis; hence such effect could not be resolved from the present strong motion data set in Greece.

Following the previously described procedure, empirical predictive relations were defined for PGA, PGV, and PGD. The results are summarized in the following equations:

$$\log PGA = 0.86 + 0.45M - 1.27 \log(R^2 + h^2)^{1/2} + 0.10F + 0.06S \pm 0.286$$
(3a)

$$log PGA = 1.07 + 0.45M - 1.35 log(R + 6) + 0.09F + 0.06S \pm 0.286$$
(3b)

$$\log PGV = -1.47 + 0.52M - 0.93 \log(R^2 + h^2)^{1/2} + 0.07F + 0.11S \pm 0.303$$
(4a)

log PGV = -1.31 + 0.52M - 0.97 log(R + 6) $+ 0.06F + 0.11S \pm 0.305$ (4b)

$$\log \text{PGD} = -4.08 + 0.88\text{M} - 1.27 \log(R^2 + h^2)^{1/2} - 0.02F + 0.25S \pm 0.424 \quad (5a)$$

 $\log PGD = -3.87 + 0.87M - 1.31 \log(R + 6)$ $- 0.04F + 0.24S \pm 0.428.$ (5b)

The last term in equations (3) to (5) expresses the standard deviation of the predicted value for each equation.

In Figure 4a we present a comparison of the observed values and our relation for PGA versus PGD reduced to a magnitude M 6.5, plotted together with the ± 1 standard deviation curves. In Figures 4b and 4c the same plots for PGV and PGD, respectively, are shown. All the proposed relations were plotted in the previous figures for "rock" soil conditions (UBC category B), that is, S = 0, for normal faulting mechanisms, that is, F = 0, and for focal depth equal to the "effective" depth of shallow events, that is, the average depth where seismic energy is released. For Greece the value that corresponds to the average focal depth being $h_0 = 7$ km, as this value was estimated using mainly macroseismic data for the area of Greece (Papazachos and Papaioannou, 1997, 1998). It is clear that Figure 4 is slightly misleading, as the reduction of all data to a common magnitude (M 6.5) neglects the magnitude-distance correlation (Fig. 2). However, examination of Figure 4 allows a rough visual inspection of the data fit of proposed relations, reduced to a typical magnitude of a strong earthquake. Therefore the true validity and quality of the fit of the proposed relations are to be evaluated from the rms error of each relation and from the additional statistical analysis presented later in the text.

Figure 4. Comparison of the horizontal (a) PGA empirical relation, (b) PGV empirical relations, and (c) PGD empirical relations, plotted together with the $\pm 1\sigma$ curves with the observed values scaled to M 6.5.

The examination of the residuals resulting from the regression analysis for each of the variables used in the regression model did not show any systematic variations as a function of the remaining variables. As an example, the distribution of the resulting residuals for each proposed relation is plotted against distance in Figure 5. It is obvious that no apparent trend can be identified in the residuals.

Comparison with Similar Predictive Relations

Comparison of the proposed horizontal PGA predictive relations with those previously proposed for the area of Greece (Theodulidis, 1991; Margaris et al., 2002), for UBC soil category B, S = 0, are shown in Figure 6a. The higher levels of PGA values predicted by Theodulidis (1991) are probably due to the multiple-step least-squares method followed in his regression analysis, which resulted in a strong correlation between coefficient c_1 and predicted values, the more rough and empirical soil categorization, and the much smaller data set used. Significant differences are observed mainly at smaller distances and for large magnitudes, with the relation proposed in this study resulting in higher values in the near field than the one proposed by Margaris et al. (2002). This is probably due to the much larger number of records in near-field distances used in the present work, amplifying the completeness of our data set in this distance range (Figs. 2 and 3).

In Figures 6b and 6c the same comparison of the proposed horizontal PGV and PGD relations is shown. We can

Figure 5. Distribution of the residuals of PGA, PGV, and PGD in terms of distance.

Figure 6. Comparison of the PGA, PGV, and PGD empirical relations (continuous line) with those proposed by Theodulidis (1991) (black dash-dotted line) and Margaris *et al.* (2002) (dashed line) for Greek data: (a) comparison for PGA empirical relations, (b) comparison for PGV relations, and (c) comparison for PGD empirical relations, for **M** 6.5 and rock soil conditions (UBC class B, S = 0).

observe some differences in the comparison of horizontal PGV relations, resulting from both the enriched data set used, as described earlier, and better classification of the recording stations with respect to local site conditions. A noticeable agreement between the relations defined in this work and the relations proposed by Margaris *et al.* (2002) for PGD for earthquakes with \mathbf{M} 6.5 is observed.

In Table 3 a comparison between the standard deviations of each proposed relation for Greece and the corresponding variance reduction are shown. It is obvious that incorporating the relocated catalog for the earthquakes that produced the Greek strong motion data set (Skarlatoudis *et al.*, 2003), as well as the homogeneous analog recording processing (Skarlatoudis, 2002; Skarlatoudis *et al.*, 2002), resulted in improved and more accurate predictive relations, mainly for PGD and PGV and to a lesser extent for PGA. The previous arguments and the comparison of the proposed relations with the ones of Margaris *et al.* (2002), which were calculated with similar regression method and with the use of a slightly smaller catalog, demonstrate the validity of the proposed relations of this study.

In Figure 7 a comparison of the horizontal PGA relations with those proposed by Ambraseys et al. (1996), Sabetta and Pugliese (1987), and Spudich *et al.* (1999) for rock (S = 0) soil conditions (UBC B class) is shown. The comparison is made for M 6.5 in order to overcome the problem related to the different magnitude scales used by Ambrasevs et al. (1996) and Sabetta and Pugliese (1987), as pointed out by Papazachos *et al.* (1997) for $M_{\rm S} < 6.0$. The comparison with the Ambraseys relation shows good agreement for a range of distances from 10 to 30 km. For distances greater than 30 km, Ambraseys's relation shows a deviation and gives higher PGA values. Considering the fact that for the derivation of this relation different data sets have been used, which come from various seismotectonic environments with different stress fields (northern Europe, Mediterranean region, etc.), different distance measures, and different regression models in the regression analysis, such a deviation can be expected. In fact, the smaller attenuation rate observed in the Ambraseys et al. (1996) relation, which included data from less active tectonic environments, is in agreement with similar observations from macroseismic data (Papazachos and Papaioannou, 1997, 1998).

Figure 7. Comparison of the PGA empirical relations (black continuous line) with those proposed by Ambraseys *et al.* (1996) (dark gray dashed line), Sabetta and Pugliese (1996) (light gray continuous line), and Spudich *et al.* (1999) (black dashed line) for **M** 6.5 and rock soil conditions (UBC class B, S = 0).

Relations proposed by Sabetta and Pugliese (1987) show higher predicted values for all epicentral distances. The use of a high percentage (50%) of thrust faulting earthquakes in their data set probably produces part of this divergence. Spudich *et al.* (1999) proposed empirical predicting relations of PGA based on records from earthquakes that occurred in mainly normal faulting (extensional regime) regions. In general, the Spudich *et al.* (1999) relation is in good agreement with the one proposed in this work, exhibiting comparable values for far-field distances, although the predicted values in the near-field range are considerably lower.

Discussion and Conclusions

Abrahamson and Silva (1997), Boore *et al.* (1997), and Campbell (1997) proposed various empirical relations (in the framework of the National Seismic Hazard Mapping Project in the United States) taking into account the type of earthquake faulting. The incorporation of such a term that accounts for the effects of focal mechanisms in the attenuation of seismic waves has been applied for the first time in empirical prediction relations for Greece. In our proposed relations a decrease in the values of coefficient c_3 is observed, as we move from PGA to PGV and PGD relations. This decrease shows that the high-frequency portion of the source spectra is affected mostly from the faulting mechanism since ground acceleration records are "richer" in high frequencies than ground velocity records, and the same applies also for ground velocity and ground displacement records. The high-frequency part of the source spectra is physically related with the estimated Brune stress drop, $\Delta\sigma$, through the corner frequency of the spectra (Boore, 1983). Many researchers showed that thrust and strike-slip faulting earthquakes exhibit higher values for Brune stress (McGarr, 1984; Cocco and Rovelli, 1989; Rovelli et al., 1991; Margaris and Hatzidimitriou, 2002) or apparent stress (McGarr and Fletcher, 2002) than normal faulting earthquakes for different regions. We should point out that the stress drop notion used here refers to its traditional use as a scaling parameter of the high-frequency acceleration spectrum, similar to the *M*-drop, ΔM , quantity proposed by Atkinson and Beresnev (1997). This dynamic stress drop derived using Brune's or other equivalent point-source model may be very different and bear a rather complex relation to the static stress-drop (fault slip as a fraction of fault dimension). Hence, the higher stress drop proposed for thrust and strike-slip events in the Aegean area does not necessarily reflect differences in source geometry (slip, dimensions) but a rather systematic higher acceleration level of the Fourier spectrum at high frequencies for such events.

However, the enhancement in high frequencies of the source spectra may be also attributed to other factors except from the high dynamic stress drop. A very critical factor that affects the frequency content of the source spectra is the dimension of the fault rupture (Thatcher and Hanks, 1973) and asperity (Kanamori, 1981). Also, high rupture velocities or local high-Q values can result in more rich high-frequency components in the spectra (Mori, 1983). In our case the data set used comes from earthquakes with equivalent moment magnitudes from M 4.5 to 7.0, that is, faults with very different dimensions; thus the coefficient c_3 was calculated independently of the fault dimension. Moreover, there are no observations of systematically higher rupture velocities for thrust and strike-slip faults (compared to normal faults) in the Aegean area, where all the examined earthquakes have occurred. In addition, the areas where most of the recorded thrust or strike-slip fault earthquakes occur (western Greece-Ionian Islands) have relatively low Q-values due to thick layers of sediments of the recording sites (usually category D). The previous observations may provide evidence that the decrease in c_3 from PGA to PGV and PGD should be attributed to the fact that thrust and strike-slip faults are simply more rich in the higher frequency part of the source spectra compared to normal faults. It should be noted that the similar values of amplification found for thrust and strike-slip faults in Greece are probably due to the fact that the examined strike-slip faults (mainly from the Ionian Islands) usually have a significant thrust component, suggesting that the tectonic setting is closer to compressional than extensional.

The coefficient c_5 in equations (3) to (5) shows a relatively large value for the PGV relation (compared to PGA) and a much larger value for the PGD proposed relation. Hence, sites for soil category D show an increase of 30%

for expected PGA values at the same distance and magnitude in comparison to soil category A/B or B. However, this amplification increases to approximately 70% and 300% when considering PGV and PGD values, respectively. This strong amplification increase is the expected evidence of the strong dependence of ground velocity and displacement on the local soil conditions. It is known that surficial layers of soft sediments are strongly affected by the low-frequency content of seismic waves, because of their relatively low resonance frequency (small elastic modulus, deposits which usually have significant thickness). This correlates with the fact that ground velocity and displacement records have enhanced low-frequency content, unlike with PGA ones, as has been mentioned before. As a result, the local site effect for sedimentary deposits is expected to be stronger for PGV and even more pronounced for PGD values, which is reflected in the increase of coefficient c5 from PGA to PGV and PGD. Unfortunately, a similar tendency is seen for the standard deviation of the proposed relations for PGV and PGD. This increase is mainly due to the limitations of the processing and filtering during the correction of strong motion records, which attempts to reduce spectral noise mostly in low frequencies (Skarlatoudis et al., 2002) that affects velocities and displacements more than acceleration, as previously explained.

Acknowledgments

We would like to thank Y. Fukushima, A. McGarr, and an anonymous reviewer for their useful comments, which helped to improve the manuscript. Professor P. Hatzidimitriou also provided an early review and made important suggestions. This work was partially supported by the Earthquake Planning and Protection Organization project "Homogeneous database of strong motion records in Greece," Number 4121-15, and the EEC project "Internet-Site for European Strong-Motion Data ISESD."
